Abstract

Climate-smart innovations are receiving increasing attention in policy dialogues for their potential to transform agricultural systems and improve the well-being and resilience of farm households. Using a recent panel data from Ethiopia merged with novel historical weather data, we provide microeconomic evidence on the household welfare effects of Conservation Agriculture (CA), a climate-smart agricultural practice. We use a panel data endogenous switching regression model to deal with selection bias and farmer heterogeneity in CA choice. The study finds that the CA practices that play a pivotal role in addressing the exigencies of rural poverty are minimum tillage, cereal-legume intercropping, and their combination. These practices significantly reduce the incidence and depth of poverty in areas prone to rainfall stress, an indication of their risk mitigation role. In contrast, crop residue retention and its combined use with minimum tillage appear not to be economically attractive CA options. The results show that CA portfolios that include minimum tillage and cereal-legume associations can accelerate efforts to reduce rural poverty and improve climate risk management. We caution against exaggerated expectations of CA's economic benefits and a rigid recommendation of CA.

Keywords: conservation agriculture; household poverty; farm heterogeneity; panel data endogenous switching regression; rural Ethiopia

1 Introduction

Rural poverty remains prevalent and an increasing concern in Sub-Saharan Africa (SSA) (Barrett et al., 2017; Hansen et al., 2018). Smallholder farmers make a significant proportion of the population that is caught in a web of poverty, mainly due to low agricultural productivity. The agriculture sector in SSA continues to underperform due to farmers' reliance on poor and unsustainable farming practices that lead to land degradation and poor soil fertility (Marenya and Barrett, 2009; Titttonell and Giller, 2013; Grabowski et al., 2016). Climate change appears to be a major source of risk for agricultural production in SSA (Cline, 2008; IPCC, 2014; Jayne et al., 2018). Agricultural households pay the heaviest toll since their livelihood is dependent on rain-fed agriculture and they operate in environments characterized by weak institutions (Dercon and Christiaensen, 2011; Kassie et al., 2015; Hansen et al., 2018). Weather-induced risks pose a threat to agricultural productivity through exacerbating production risks, increasing risk exposure (Di Falco et al., 2011), and altering agricultural households' incentives to innovate and invest in remunerative activities (Dercon and Christiaensen, 2011; Emerick et al., 2016). Low and erratic rainfall also leads to soil moisture stress, another important constraint to agricultural production (Thierfelder et al., 2017). With farmers facing climate variability and extremes, soils with low moisture content could lead to low crop yields and crop failure that would exacerbate rural poverty (Dzanku et al., 2015; Asfaw et al., 2016b).

Due to the increasing challenges of climate change, shrinking agricultural frontiers and declining soil fertility (Marenya et al., 2015; Grabowski et al., 2016), feeding a surging population (that is expected to double to 2 billion by 2050) and alleviating rural poverty is a challenge in the current agricultural development policy (Di Falco et al., 2011; van Ittersum et al., 2016). The solution to address these intertwined challenges requires a new paradigm for transforming African agriculture. Since the farming systems of SSA are capital-deficient, prone to weather extremes and have poor quality soils (Marenya and Barrett, 2009; Kassie et al., 2015), the development and promotion of technologies and practices that could help to improve soil quality and increase crop yields have no parallels in the process of African agricultural transformation and to address the multiple challenges of climate change and low agricultural production (Wheeler and Von Braun, 2013; Dzanku et al., 2015). Sustainable intensification is uniquely positioned as a way forward for African agricultural transformation (Pretty et al., 2011; Garnett et al., 2013; Godfray and Garnett, 2014; Juma et al., 2013). One of the options for promoting sustainable agricultural production is the utilization of "climate-smart" agricultural technologies and practices that could support agricultural production and enhance adaptive capacity by cushioning against the effects of climate change (Bradshaw et al., 2004; Di Falco et al., 2011; Lipper et al., 2014; Asfaw et al., 2016b). As such, climate-smart agricultural practices are receiving greater attention in agricultural development policymaking to harmonize economic and environmental concerns (Kpadonou et al., 2017; Jayne et al., 2018).

Conservation agriculture (hereinafter CA) is an example of a group of climate-smart agricultural practices that promote sustainable production and can improve households' resilience to weather shocks (FAO, 2013; Giller et al., 2011; Pittelkow et al., 2015). CA is a cropping system founded on three practices: minimum or reduced tillage, cereal-legume rotation or intercropping, and the retention of crop residues or mulch (Hobbs, 2007; Ito et al., 2007; Kassam et al., 2009). Being central to the sustainable intensification concept, CA has increasingly been promoted as a viable alternative to conventional farming. It is believed that CA helps farm households address their poor production outcomes, manage climate risks, and prevent environmental degradation (Hobbs et al., 2008).¹ CA can play both a climate change adaptation

¹Although CA provides food security, climate change adaptation and mitigation benefits (FAO, 2010, 2013; Lipper et al., 2014), smallholder farmers will benefit more from enhanced food security/agricultural productivity, increased income and greater resilience (Neufeldt et al., 2011).

(self-insurance) and mitigation (self-protection) role against environmental (rainfall and soil fertility related) shocks (Ehrlich and Becker, 1972; Hanley et al., 2007). Thus, CA is among the production technologies and farm practices that concentrate on addressing the links between climate change, soil fertility, farm profits, and rural poverty.

The literature on the economics of CA seems to be dominated by a bulk of studies that focus on the drivers of CA adoption (Knowler and Bradshaw, 2007; Andersson and D’Souza, 2014; Arslan et al., 2014; Grabowski et al., 2016). Existing studies show that the factors influencing CA adoption in SSA include high weed pressure due to reduced tillage, labor constraints during weeding time (Giller et al., 2009; Pannell et al., 2014; Lalani et al., 2016), lack of knowledge about CA and its benefits (Lalani et al., 2016), the time lag between adoption and realization of benefits (Thierfelder et al., 2017), and competition for resources (Baudron et al., 2014; Tessema et al., 2015). Studies related to this body of the literature have also tried to delve into the debate surrounding the suitability, effectiveness, and potential benefits of CA in SSA (Giller et al., 2009; Rodriguez et al., 2017). One important concern is the high opportunity cost of crop residues (biomass) which are valuable resources with alternative uses for farming households in SSA. Crop residues can be used as livestock feed, an energy source, building materials, source of cash, or simply burnt in the field (Jaleta et al., 2015; Rodriguez et al., 2017). Thus, the benefits of recycling crop residues back into the cropping system as mulch may not be worth the trade-off of giving up its other benefits.

Another strand of the literature on the economic benefits of CA is devoted to analyzing its productivity impacts (Teklewold et al., 2013; Arslan et al., 2015; Ngoma et al., 2016; Jaleta et al., 2016; Teklewold and Mekonnen, 2017; Michler et al., 2018; Ngoma, 2018), production risk-reducing effects (Kassie et al., 2015; Michler et al., 2018), and adaptive capacity benefits (Kassie et al., 2015; Arslan et al., 2015, 2017; Steward et al., 2018). However, the literature on the economics of CA that focuses on its welfare impacts is rather sparse and inconclusive (Hansen et al., 2018; Tambo and Mockshell, 2018). More specifically, there is limited evidence that identifies the impact of CA on household poverty (Hansen et al., 2018). Among the few studies is Abdulai (2016) which finds that CA reduces the incidence of household poverty in Zambia. Farris et al. (2017) also show that an increase in farm profit due to CA reduces poverty incidence in Uganda. These studies are based on cross-sectional data which may limit the analysis from fully controlling for unobserved endogeneity (Pannell et al., 2014; Michler et al., 2018). Using panel data econometrics with economic surplus analysis, Kassie et al. (2017) find that legume-diversification, an important anchor of CA, contributes to poverty reduction in Ethiopia when used with fertilizer and improved maize seeds. While informative, results from analysis of only a single CA practice do not provide adequate evidence for exploring the potential incentives for the wider scale adoption of a combination of CA practices that would generate higher returns. Khonje et al. (2018) investigate the impact of improved seeds and CA using panel data from Zambia and find that joint adoption of the technologies had greater impact on crop yields, income and poverty. However, the authors adopt a holistic approach to define CA adoption. In fact, Giller et al. (2009) argue that lack of evidence on the economic impacts of CA disaggregated by its different components makes the refinement, targeting, and extension of CA difficult.

This study contributes to the literature by establishing an empirical link between CA and household poverty in Ethiopia. Poverty is pervasive in rural Ethiopia where agriculture is the major source of income and livelihood (Abro et al., 2014; Bachewe et al., 2017; Michler and Josephson, 2017; Verkaart et al., 2017). The Ethiopian economy depends on agriculture, which employs a majority of the population (Di Falco and Veronesi, 2013; Abro et al., 2014; Bachewe et al., 2017) but is primarily rain-fed and prone to weather-related shocks and stresses such as spatial and temporal rainfall variability and drought (Teklewold et al., 2013; Di Falco and

Veronesi, 2013). Harvest failure due to weather events is the biggest cause of risk-related hardship in the country with adverse effects on household welfare (Dercon, 2004; Dercon et al., 2005). Low agricultural production, demographic pressures and other structural and institutional impediments lead to persistent poverty and impaired economic development in the country.

CA is a potential sustainable agricultural practice to address climate change and poor soil fertility, and to improve crop productivity while preserving the natural resource base in Ethiopia (Marennya et al., 2015; Jirata et al., 2016).² Promotion of CA in Ethiopia began in 1998 through the joint promotion and demonstration of the technology on farmers' plots by Sasakawa Global (SG2000), Makobu and regional agricultural development bureaus (Jirata et al., 2016). Since the initial trials, organizations including FAO, International Maize and Wheat Improvement Center (CIMMYT) and Agricultural Transformation Agency (ATA) of Ethiopia promoted CA across the country through field demonstrations, introducing different CA equipments (e.g., jab planters and oxen-drawn seed and fertilizer planters) and training of extension agents and farmers (Jirata et al., 2016). Ethiopia's Climate Resilient Green Economy strategy also advocates CA (mainly zero or reduced tillage) as a climate change adaptation option (FDRE, 2011 in Teklewold and Mekonnen (2017)). Despite these efforts, we know little how CA affects rural poverty.

We investigate whether CA has impact on household welfare and through the pathways of increased productivity, resource conservation (and cost reducing) and risk-reduction. The study uses panel household survey data provided from the Living Standards Measurement Study-Integrated Surveys on Agriculture (LSMS-ISA) of the World Bank combined with a rainfall data extracted from the Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS). The rich data allows examination of the many socioeconomic, farm characteristics and biophysical (rainfall and soil) conditions in determining variation in CA use and household poverty. The empirical strategy relies on panel endogenous switching regression model that accounts for farm heterogeneity in the decision to use CA. The results help explain the unstable and low uptake of CA (particularly combination of CA practices) and inform the debates about CA's attractiveness in SSA. Overall, the study provides evidence that could help in targeting CA initiatives and interventions for climate risk management, agricultural transformation and poverty reduction.

The rest of the paper is structured as follows. Section 2 presents a theoretical model that guides the empirical strategy described in section 3. Section 4 describes the data and their sources. Section 5 presents the results and the last section concludes.

2 Theoretical framework

This study estimates the impact of CA on household poverty. We consider households' decision to use CA as a random utility framework in which they choose one or more CA practices that increase utility (Tambo and Mockshell, 2018). We think of households' decision as a constrained optimization problem at the beginning of the agricultural season based on available information, the farmers' expectations regarding the coming year's growing conditions, and the relative costs and benefits of CA (Suri, 2011; Pannell et al., 2014).

The farmer makes polychotomous decision whether to adopt CA: minimum tillage (T), crop residue retention or mulch (R) and cereal-legume intercropping (C), and their combinations. The

²Various projects and programs, including the Sustainable Land Management Programmes (SLMP1 and SLMP2), Managing Environmental Resources to Enable Transitions to more Sustainable Livelihoods (MERET), Productive Safety Nets Programme-Public Works (PSNP-PW) have been part of sustainable land management and climate change adaptation activities in Ethiopia (Jirata et al., 2016). A notable example is the SLMP2, which advocates sustainable land management and intensification techniques such as mulching, intercropping or crop rotation, and no-till.

choice of the three CA practices in isolation or in combination leads to eight mutually exclusive CA choice sets including an empty set in which none of the CA practices is adopted (see Table 1). For each CA practice or combination of practices, there is a corresponding outcome level. We are interested in the outcome differences between the CA users and the counterfactual - the outcomes had the household not used CA. This difference is called the “treatment effect” (Rubin, 1978) which we can call the “CA use effect”.

The measurement of CA use and its impact on household poverty is complicated by the non-separability of households’ production decisions and consumption preferences (Singh et al., 1986; de Janvry et al., 1991). Farm households in rural Ethiopia operate in an environment characterized by weak institutions and incomplete markets (Marenya et al., 2015; Teklewold et al., 2013; Verkaart et al., 2017). The absence of formal risk management and pooling mechanisms and weak markets make production decisions (e.g. CA adoption) and consumption preferences non-separable. Absent or imperfect formal insurance markets means risk averse farm households do not have an incentive to engage in high return but potentially risky activities (Dercon and Christiaensen, 2011; Kassie et al., 2015). Imperfect rural labor markets, information asymmetry and high transaction costs constrain the capacity of resource poor households to adopt labor and knowledge intensive technologies and farming practices such as CA (Kpadonou et al., 2017). Imperfect access to credit also limits households’ investment in capital-intensive innovations (Mutenje et al., 2016). The seasonality and underdevelopment of output markets (e.g., grain markets) often discourage technology investments and could limit the implementation of CA practices such as cereal-legume diversification and crop residue retention in mixed crop-livestock production farming systems (Tessema et al., 2015).

CA use decision is also determined based on differences in expected net farm returns (farm profits) between CA and Conventional farming (CF) scenarios. Following Suri (2011), the profit functions for CA and non-CA (CF) farmers at time t can be represented as different between revenue and costs as follows

$$\pi_{it}^{CA} = p_{it}Y_{it}^{CA} - \sum_{j=1}^J \omega_{jit}X_{jit}^{CA} \quad (1)$$

$$\pi_{it}^{CF} = p_{it}Y_{it}^{CF} - \sum_{j=1}^J \omega_{jit}X_{jit}^{CF} \quad (2)$$

where Y_{it}^{CA} and Y_{it}^{CF} are the vector of crop yields for CA and CF farmers, respectively. p_{it} is a vector of crop prices which is assumed to be same for CA and CF; X_{it} and w_{it} are vectors of inputs and input prices respectively.

Let the expected profit (income) from CA and CF be denoted by π_{it}^{*CA} and π_{it}^{*CF} , respectively. The farmer decides to choose CA over CF if the optimized farm profit from using CA exceeds the optimized farm profit from without CA, i.e., when $\pi_{it}^{*CA} > \pi_{it}^{*CF}$. This could be written as the following optimality condition:

$$\left(Y_{it}^{*CA} - \sum_{j=1}^J \frac{\omega_{jit}}{p_{it}} X_{jit}^{*CA} \right) > \left(Y_{it}^{*CF} - \sum_{j=1}^J \frac{\omega_{jit}}{p_{it}} X_{jit}^{*CF} \right) \quad (3)$$

To understand the impact of CA on household poverty, we must consider the various pathways through which CA would affect household poverty. The poverty reducing effects of CA could primarily be channeled through its farm level impacts. CA would affect household poverty primarily through its effect on aggregate crop productivity (crop yields) and farm returns (crop income). Assuming crop and input prices to be same for CA and non CA farmers (from the

profit functions), CA use decisions based on farm profits will primarily depend on yield differences across CA and CF. Differences in yield and input use are very likely to lead to differences in farm income (profit) and cost of production that would ultimately affect welfare. Crop yield improvements will be obtained from the agronomic benefits of CA such as improved soil structure, increased organic matter, and reduced moisture stress (Tambo and Mockshell, 2018). The resulting increased crop yields may subsequently increase crop income and hence household consumption expenditure (Abdulai, 2016). Over several seasons, the incremental increase in consumption or income could help households grow out of poverty.

CA would affect household poverty through reducing production costs (Tambo and Mockshell, 2018) and mitigating production risks (Teklewold et al., 2013; Kassie et al., 2015) that would enhance farm income. In addition, CA practices could save time and labour (especially in peak seasons) that can be reallocated to alternative income-generating activities. On the other hand, CA may increase household labour requirements for weeding if pesticides are not used, and thus reduce household income and consumption expenditure (Giller et al., 2009; Arslan et al., 2014). The other key channel through which CA would affect household poverty is through its risk buffering effect (Arslan et al., 2017). Using CA means a better quality of soil and higher resistance to climate (environmental) risks (Tambo and Mockshell, 2018). As a result, households that practice CA are less likely to face risk of crop failure.

3 Empirical strategy

Estimating the impact of CA on household poverty and farm level outcomes is inherently subject to various endogeneity problems. Since CA use behaviour is not random, farmers' CA technology choice decision is likely to be determined by unobserved characteristics (such as farm management skills and ability, individual motivation, openness to innovation, preferences, etc) that would also be correlated with poverty and farm level outcomes (Mundlak, 2001; Suri, 2011). When households are not randomly assigned to CA users and non-users, they will self-select into CA choice based on their capacity and expected returns which are heterogeneous (Wu and Babcock, 1998; Marenja and Barrett, 2009; Suri, 2011; Pannell et al., 2014). The choice to use CA may also be driven by unobserved farm characteristics such as soil fertility or soil quality. CA choice could also be affected by time-invariant unobserved factors and time-varying (transitory) shocks that may also affect household poverty. Farmers who actively choose no-till or reduced tillage for soil conservation or productivity-enhancing reasons might also be more likely to be different (or have different farms) than farmers who practice de facto no till systems because they do not have access to technology to facilitate tilling. Moreover, there may be heterogeneity in returns to CA (e.g., in terms of yield, cost or risk reduction) such that farmers with high returns to CA are the ones that practice CA (Suri, 2011). This indicates that unobserved farmer-specific comparative advantage (the gain from CA choice) might influence the decision to use CA (Suri, 2011). Regression of the outcomes on CA use without correcting for the potential self-selection and unobserved heterogeneity may lead to erroneous estimates for the returns to CA adoption.

With panel data, the impact of CA can be recovered by addressing some of the endogeneity concerns raised above. For instance, fixed effects (FE) can help to control for unobserved endogeneity through eliminating the effect of time-invariant characteristics. However, the use of FE is inadequate to estimate the effects of CA for two reasons (Kassie et al., 2017). First, FE models assume that both observed and unobservable factors have homogeneous effect on household poverty for both CA users and nonusers. This is a stringent assumption since the economic outcomes of CA use can be heterogeneous due to both observed and unobserved factors (Suri, 2011; Pannell et al., 2014; Kassie et al., 2017). Second, standard regressions such as FE assume that unobservable time-invariant variables are the only omitted variables that affect CA use and the outcomes. This assumption is less likely to hold because households might move in

and out of CA use during the course of the panel due to changes in unobservable factors that could also affect the outcomes (Suri, 2011). Thus, standard regressions cannot help us take full account of farmer heterogeneity.³

To circumvent selection bias due to time-invariant and time-varying unobservables, we employ panel endogenous switching regression (ESR) model (Malikov and Kumbhakar, 2014). Since households face CA use decision of a polychotomous nature, we utilize a multinomial ESR (MESR) model. Since separate outcome regressions are estimated for CA and non-CA households, the MESR allows interaction between the CA technology set choice and the control variables to capture the effect of CA technology choice on the shift of the intercept and slope of the outcome equation (Di Falco and Veronesi, 2013; Kassie et al., 2017). Additional advantage of the MESR method is that it enables the construction of a counterfactual based on returns to characteristics of CA users and non-users (Kassie et al., 2017). The framework also helps us explore in depth the CA use decision and impact of the CA practices individually and in combination. Likewise, it enables us capture potential interrelationship among the specific CA practices and to identify the CA package that yields the highest payoff (Wu and Babcock, 1998).

Following Malikov and Kumbhakar (2014), we begin with the following generalized panel data switching regression model

$$y_{it,j} = \begin{cases} x_{it,j}\beta_j + v_{ij} + \nu_{it,j} & \text{if } C_{it} = j \\ - & \text{otherwise} \end{cases} \quad (4)$$

with

$$C_{it,j}^* = z_{it,j}\gamma_j + u_i + \eta_{it,j} \quad (5)$$

where $i = 1, \dots, N$ indexes the household, $t = 1, \dots, T$ indexes time and $j = 1, \dots, J$ denotes the regimes. y_{it} is the outcome of interest (poverty or farm level outcomes) and C_{it} denotes CA choice (the practices in isolation or in combination). $x_{it,j}$ and $z_{it,j}$ are a vector of covariates such as household and farm characteristics and biophysical factors that may overlap. v_{ij} and u_i are household-specific unobserved effects that are allowed to be correlated with the covariates. $\nu_{it,j}$ and $\eta_{it,j}$ are disturbance terms that are assumed to be orthogonal to $x_{it,j}$ and $z_{it,j}$. The outcome variable $y_{it,j}$ will be observed conditional on the selected CA regime j . $C_{it,j}^*$ is a latent variable that govern the regime selection or switching (CA choice) with observable categorical responses. β_j and γ_j are parameters to be estimated. Least squares estimation of the outcome equation may not give consistent estimate of β_j since possible correlation between $\nu_{it,j}$ and $\eta_{it,j}$ may also introduce some correlation between the explanatory variables and the disturbance terms in the outcome equation (Bourguignon et al., 2007). To address this and other econometric concerns, the above model is estimated using a multinomial endogenous switching regression (MESR) model in a two-stage framework (Bourguignon et al., 2007; Malikov and Kumbhakar, 2014).

First stage: Multinomial logit model with farmer's heterogeneity

The first stage involves modelling the drivers of CA choice following a random utility framework in which at each time period t , a farmer i chooses a CA technology set that maximizes expected utility. Let the utility from choosing a CA technology set j be represented by the latent variable $C_{it,j}^*$. A household chooses a CA technology set j if its utility or expected return outweighs the utility that could be obtained from another set k i.e., if $\varepsilon_{it,j} = \max_{k \neq j} (C_{it,k}^* - C_{it,j}^*) < 0$.

³Standard regressions such as Ordinary Least Squares (OLS) or Fixed Effects and Instrumental variables (IV) methods cannot help us account for farmer heterogeneity. If OLS or FE is used to estimate the impact by introducing dummy for CA, the coefficient suggests the impact to come from those who switch CA during the course of the panel (Suri, 2011).

Following [Di Falco and Veronesi \(2013\)](#) and from equation 5, we specify the latent model that describes farmer’s CA adoption behaviour as

$$C_{it,j}^* = Z_{it,j}\gamma_j + u_i + \eta_{it,j} \quad (6)$$

with

$$C_{it} = \begin{cases} 0 & \text{iff } C_{it,0}^* > \max_{k \neq 0} (C_{it,k}^*) \\ \vdots \\ J & \text{iff } C_{it,J}^* > \max_{k \neq J} (C_{it,k}^*) \end{cases} \quad (7)$$

In equation 6, $Z_{it,j}$ is a vector of variables that would affect the probability of choosing CA technology set j . Likewise, u_i and $\eta_{it,j}$ represent the household-specific heterogeneity and time-varying unobserved factors or idiosyncratic errors, respectively. The Z_{it} and the idiosyncratic unobserved stochastic component are assumed to be uncorrelated (i.e. $E(\eta_{it,j}|Z_{it,j}) = 0$). Under the assumption that $\eta_{it,j}$ is independent and identically Gumbel distributed across all CA sets (the independence of irrelevant alternatives or IIA hypothesis) ([Bourguignon et al., 2007](#)), equation 6 leads to multinomial logit model ([McFadden, 1973](#)) with farmers’ heterogeneity of the following form

$$p_{it,j} = Pr(C_{it} = j|Z_{it}, u_i) = \frac{\exp(\alpha_j + Z_{it}\gamma_j + u_i)}{\sum_{k=1}^J \exp(\alpha_k + Z_{it}\gamma_k + u_i)}, j = 1, \dots, J \quad (8)$$

where $p_{ij,t}$ is the probability that household i will choose the CA set j at time t . Z_{it} is a matrix of observable household characteristics (e.g., gender, age and education of the household head and household size) that are major factors determining labor availability, human capital, and risk preference, and hence CA use ([Arslan et al., 2017](#)). Wealth indicators (farm size, asset wealth, livestock holding, credit access) are also included to control for factors such as risk and time preferences that determine the ability of farm households to introduce CA in their farming systems ([Tanaka et al., 2010](#); [Pannell et al., 2014](#); [Tessema et al., 2015](#)). We control for access to extension service, proximity to markets, road, soil nutrient availability and climate related variables. We also add a time period and region dummies to capture temporal and spatial differences in agro-ecology, price, and institutions ([Suri, 2011](#); [Kassie et al., 2017](#)). u_i denotes time-invariant unobserved factors or farmer heterogeneity. α_j represents the specific constant term of CA technology set j . The parameter of interest is γ_j which measures the average partial or marginal effect of the determinants of CA adoption.

Equation 8 is estimated using pooled multinomial logit model with correction for unobserved heterogeneity using the [Mundlak \(1978\)](#) device ([Wooldridge, 2002](#)). The Mundlak approach helps us model the time-invariant individual unobserved effect (u_i) as a linear projection of the averages of all time-varying observed variables as: $u_i = \pi \bar{Z}_i + a_i$. In addition to controlling for potential unobservable household and farm-specific effects, the Mundlak approach helps to avoid the problem of incidental parameters that might arise from using fixed effects in the multinomial logit model. The approach enables us generate consistent estimates since it accommodates dependence between unobserved effects and the explanatory variables in the model. From the first-stage estimates, we derive Inverse Mills Ratio (IMR) terms that serve as selectivity correction terms in the second stage.⁴

⁴The selection correction terms are computed for each regime separately as: $\lambda_{it,j} = \frac{\phi[J_{\varepsilon_{jit}}(\cdot|\Gamma)]}{\Phi[J_{\varepsilon_{jit}}(\cdot|\Gamma)]}$ where $\phi(\cdot)$ is the standard normal probability density function (pdf) and $\Phi(\cdot)$ is the standard normal cumulative distribution function (cdf). $J_{\varepsilon_{it,j}}(\cdot|\Gamma) = \Phi^{-1}(\Lambda_{\varepsilon_{it,j}}(\cdot|\Gamma))$ where $\Lambda_{\varepsilon_{it,j}}(\cdot)$ is the cdf of $\varepsilon_{it,j}$ and $\Gamma = \{Z\gamma_j; \bar{Z}\pi_j; j = 1, \dots, J\}$. The distributional and linearity assumptions and alternative approaches are discussed by [Malikov and Kumbhakar \(2014\)](#) and [Bourguignon et al. \(2007\)](#).

Second stage: Outcome equations

In the second stage, we estimate Ricardian-type outcome equation models (Mendelsohn et al., 1994) conditional on the selected CA technology set with selectivity correction terms obtained from the first stage, along with correction for potential unobserved heterogeneity using the Mundlak device. The second stage involves estimating the impacts of the selected CA choice set on household poverty and the farm level outcomes. Each CA regime the household faces when making the CA technology choice leads to separate outcome equations. The treatment effects of interest, in this case, consist of various binary comparisons of the actual outcomes for CA users (any practice or combination) and the counterfactual scenario. Because, for each sample household, the dependent variable is observed for the selected CA technology set only, a simple comparison of the outcomes for CA users (the selected regime) and nonusers (reference category) will yield inconsistent estimates. To get consistent estimates of the parameters of interest, we estimate the outcome equations following the approach by Bourguignon et al. (2007) that takes into account the correlation between the error terms of the multinomial logit model and the outcome equations.

The outcome equations for each possible regime j with selection bias correction is specified as

$$\begin{aligned} \text{Regime 0 : } Y_{it,0} &= X_{it,0}\beta_0 + \hat{\lambda}_{it,0}\sigma_0 + (\hat{\lambda}_{it,0}T)\psi_0 + v_{i0} + \epsilon_{it,0}, & \text{if } j = 0 \\ \text{Regime J : } Y_{it,J} &= X_{it,J}\beta_J + \hat{\lambda}_{it,J}\sigma_J + (\hat{\lambda}_{it,J}T)\psi_J + v_{iJ} + \epsilon_{it,J}, & \text{if } j = 1, \dots, J \end{aligned} \quad (9)$$

where $j = 0$ denotes the null category where neither of the CA practices nor their combinations is used by the farmer, and $j = 1, 2, \dots, J$ indicates use of any CA practice or a combination of practices. $Y_{it,j}$ represents the outcomes related with the selected regime j ($j = 0, \dots, J$). X_{it} represents a vector of control variables defined above. Since the factors that would affect CA choice may also affect household poverty and the farm level outcomes, the second stage outcome regressions can share the covariates included in the first stage regression. $\hat{\lambda}$ are the predicted inverse mills ratios (IMRs) derived from the multinomial logit selection equation (8) to capture time-varying unobservable effects. σ is the covariance between the error terms of CA choice and the outcome equations. In addition to the IMRs, we introduce the interaction of the IMRs and year (T) as $\hat{\lambda}_{it,j}T$ based on Wooldridge (2002) for estimation of unbalanced panel data models (Kassie et al., 2017). This allows for different correlations between the idiosyncratic errors and the correlations to be different across time. v represents the time-invariant unobservable factors. The parameters of interest are β , ψ and σ .

We follow Wooldridge (2002) and Malikov and Kumbhakar (2014) to estimate pooled ordinary least squares (OLS) models for the outcomes. Pooled models are preferred since selection bias correction by adding the IMR to the second stage and using standard fixed effects might lead to inconsistent estimates (Wooldridge, 2002; Kassie et al., 2017). We employ OLS for continuous outcomes equations and linear probability models (LPM) for binary outcome equations (Dercon et al., 2009; Dercon and Christiaensen, 2011; Michler and Josephson, 2017). As in the first stage, we utilize the Mundlak (1978) approach to attenuate the effects of unobserved heterogeneity. To this purpose, we parameterise the time invariant unobserved variable (v_i) by replacing it with its linear projection onto the time averages of all time-varying explanatory variables as: $v_i = \eta\bar{X}_i + b_i$ with $b_i \sim IIN(0, \sigma_b^2)$ and $E(b_i|\bar{X}_i) = 0$. The use of the Mundlak specification to define correlated effects in both stages helps us conserve degrees of freedom (Malikov and Kumbhakar, 2014). Since the second stage outcome regressions include estimates from the first stage selection model, we correct the standard errors using bootstrapping.

The significance level of our treatment effects will not be biased due to lack of exclusion restrictions because we estimate separate outcome regressions for CA users and nonusers (Malikov

and Kumbhakar, 2014; Kassie et al., 2017). However, it is often important to use exclusion restrictions in addition to those automatically generated by the nonlinearity of the IMRs obtained from the selection model. Previous studies used past experience of extreme weather events (e.g., drought) and information sources (e.g., government extension, farmer-to-farmer extension, information from radio) as selection instruments in related impact evaluation studies (Di Falco et al., 2011; Di Falco and Veronesi, 2013; Kassie et al., 2015; Teklewold and Mekonnen, 2017). To remain within the spirit of these studies, we use community level improvement in agricultural extension services related to crop production and natural resources management as exclusion restriction. Following Di Falco et al. (2011), we test the validity of the selection instruments by performing a simple falsification test. The results confirm that the excluded variables have a significant effect on CA (significant for some of the CA practices) but do not exert any significant effect in the outcome equations (Table 15 in the Appendix).

Counterfactual Analysis and Treatment Effects

To assess the effect of the CA technology set choice on the outcomes (the treatment effect on the treated), we estimate the expected actual (observed) outcomes and the counterfactual outcomes for a farm household that uses CA technology set j with correction for selection bias and endogeneity. The actual expected outcomes are computed as:

$$E(Y_{it,J}|j = J) = X_{it,J}\beta_J + \hat{\lambda}_{it,J}\sigma_J + (\hat{\lambda}_{it,J}T)\psi_J + \bar{X}_{iJ}\gamma_J, j = 1, 2, \dots, J \quad (10)$$

where \bar{X}_{iJ} denotes the mean of the time-varying explanatory variables introduced to control for the effect of unobserved factors.

Similarly, the counterfactual expected value of the outcomes for farm households with a CA technology set j that contains one or more CA components is given as:

$$E(Y_{it,0}|j = J) = X_{it,J}\beta_0 + \hat{\lambda}_{it,J}\sigma_0 + (\hat{\lambda}_{it,J}T)\psi_0 + \bar{X}_{iJ}\gamma_0, j = 1, 2, \dots, J \quad (11)$$

In equation 11, the parameters β_0 , σ_0 , ψ_0 and γ_0 are coefficients obtained from estimation of the outcomes without a CA technology set ($j = 0$) and the other variables are as they are defined above. Equation 11 represents the outcome from a CA technology set j ($j = 1, \dots, J$) CA users would have obtained if the returns (coefficients) on their characteristics (X, \bar{X} , and $\hat{\lambda}$) had been the same as the returns (coefficients) on the characteristics of the non-users (Teklewold et al., 2013; Kassie et al., 2017).

The average treatment effect on the treated (ATT), which is the measure of the average effect of CA on the outcomes, is estimated taking the difference between equation 10 and equation 11 (Kassie et al., 2017; Khonje et al., 2018) as follows

$$\begin{aligned} ATT &= E(Y_{it,J}|j = J) - E(Y_{it,0}|j = J) \\ &= (\beta_J - \beta_0)X_{it,J} + (\sigma_J - \sigma_0)\hat{\lambda}_{it,J} + (\psi_J - \psi_0)(\hat{\lambda}_{it,J}T) + (\gamma_J - \gamma_0)\bar{X}_{iJ} \end{aligned} \quad (12)$$

The first term of equation 12 $((\beta_J - \beta_0)X_{it,J})$ indicates the change in the outcomes due to the differences in returns to observed characteristics. The second and third terms $((\sigma_J - \sigma_0)\hat{\lambda}_{it,J}$ and $(\psi_J - \psi_0)(\hat{\lambda}_{it,J}T)$) indicate the change in the outcomes due to differences in returns that attribute to time-variant unobserved characteristics. The last term $((\gamma_J - \gamma_0)\bar{X}_{iJ})$ is attributed to outcome changes because of differences in time-invariant unobservables.

4 Data and Descriptive Statistics

4.1 Household and Rainfall Data

The data come from the Ethiopian Socioeconomic Survey (ESS) administered through the Living Standards Measurement Study-Integrated Surveys on Agriculture (LSMS-ISA) initiative of the World Bank in collaboration with the Central Statistical Authority of Ethiopia.⁵ The household survey collects detailed information on household socioeconomic characteristics, non-agricultural household enterprise, household assets, household consumption expenditure, shocks and coping strategies. The agriculture survey collects information on land holdings, agricultural inputs, crop production and disposition patterns and livestock ownership. Moreover, the ESS collects information on extension services related to crop production and natural resources management at the community level. Both the households and their plots are georeferenced using global positioning system (GPS) that enables inclusion of relevant biophysical factors such as rainfall, temperature and soil nutrient constraints in the analysis.

The LSMS-ISA provides high-quality household consumption data for poverty analysis (Faris et al., 2017). We utilize information on socioeconomic variables such as farmer characteristics (e.g. age, gender, education, household size), wealth (land holding, livestock wealth, asset holding, credit access), farm management (e.g. input use, plot characteristics, etc), biophysical factors (e.g. soil, temperature, rainfall) and the enabling environment (e.g. markets, extension services, proximity to road) as controls in the analysis. The panel nature of the data set allows us to study variation in CA use and household poverty, both of which are important considerations for policy making. While the ESS has three waves (2011/12, 2013/14 and 2015/16), we do not use the 2011/12 wave since no information is collected about crop residue retention and minimum tillage. Therefore, this paper is based on data from the latest two waves (2013/14 and 2015/16) with a focus on the rural sample. Attrition for the rural household sample is 1.5% across the two waves. After thorough data cleaning and exclusion of observations with missing values, final analysis is undertaken with an unbalanced panel of 6,102 rural households.

We extract historical rainfall data from the Climate Hazards Group InfraRed Precipitation with Station data (CHIRPS), a thirty year quasi-global rainfall dataset that spans $50^{\circ}S - 50^{\circ}N$. CHIRPS incorporates 0.05° resolution satellite imagery with *in-situ* station data to create a gridded rainfall time series (Funk et al., 2015; Michler et al., 2018). We make use of the geographical coordinates for the village boundaries from the LSMS-ISA data to take the average rainfall for the months within the village from 1981 to 2014. Then, we aggregate the village level monthly rainfall data to the annual and seasonal levels. From the rainfall data, we compute the historical average and standard deviation of rainfall to capture the short and long term climate variability. The amount of rainfall during the growing season preceding the survey year is also included as proxy for water stress or availability. The rainfall variables help to control for the effect of farmers' risk profile and expectations on CA use.

4.2 Conservation agriculture use patterns

A difficulty in empirical studies on the farm level economics of CA is deciding which practice(s) to count as CA (Pannell et al., 2014; Michler et al., 2018). In this study, the three pillars of CA considered are minimum or reduced tillage (T), crop residue retention or mulching (R) and cereal-legume intercropping (C). We define minimum tillage as a binary variable taking a value of 1 if the households uses either zero or reduced tillage (only one plough pass) on at least one of the plots (Kassie et al., 2015). Crop residue retention, another anchor of CA, is defined as a dummy variable taking value of 1 if the household leaves any crop residue/mulch on the plot

⁵Details of the survey including sample size, sampling methods, data and other supporting materials are provided in the website: www.worldbank.org/lms-isa.

surface.⁶ Cereal-legume intercropping is another essential part of CA systems and a climate-risk reduction strategy. We exploit the crop level information to create an indicator for cereal-legume intercropping which is defined as whether the household cultivates cereals with legume crops on at least one plot.⁷ Then, we generate a multinomial choice variable by categorizing households according to their adoption of the 3 CA practices in isolation and/or in combination which leads to 8 possible CA technology options. Conventional farming or traditional cultivation practices are defined as everything else other than the 3 CA practices (Michler et al., 2018). Our pragmatic approach, although not ideal, is in line with previous literature (Pannell et al., 2014; Arslan et al., 2014). More important, we adopt a more practical definition of CA given the context of Ethiopia (Marennya et al., 2015; Tessema et al., 2015; Teklewold and Mekonnen, 2017).

Table 1: Pattern of CA combinations adoption (%)

CA sets	Frequency (%)		
	2013	2015	Pooled
Conventional farming or no CA ($T_0R_0C_0$)	36.42	51.01	43.66
Minimum tillage only ($T_1R_0C_0$)	50.8	32.41	41.67
Crop residue retention only ($T_0R_1C_0$)	0.98	2.44	1.70
Cereal-legume intercropping only ($T_0R_0C_1$)	2.86	3.04	2.95
Min. tillage & crop residue only ($T_1R_1C_0$)	2.11	5.45	3.77
Min. tillage & cereal-legume intercrop only ($T_1R_0C_1$)	6.41	4.66	5.54
Crop residue & cereal-legume intercrop only ($T_0R_1C_1$)	0.23	0.30	0.26
Comprehensive CA (all 3 practices) ($T_1R_1C_1$)	0.20	0.69	0.44

Note: Each mutually exclusive CA set consists of a binary variable for the CA practices minimum tillage (T), crop residue retention (R) and cereal-legume intercropping (C) where the subscript 1 shows use and 0 denotes nonuse of the particular technology set. The sample sizes are 3,075 and 3,027 for 2013 and 2015, respectively. The proportion of households using the CA practices (in contrast to the mutually exclusive category presented here) over the two periods along with proportion difference test is provided in Table 8 (Appendix).

Table 1 summarizes the pattern of CA adoption over the two periods. After about 20 years of promotion, the adoption of the CA practices in Ethiopia is low and uneven. The proportion of households that practice minimum tillage only significantly diminished from 51% in 2013 to about 32% in 2015. The adoption rates are comparable with the study by Tsegaye et al. (2008) that report a 57% adoption rate of a component or combination of conservation tillage technology in Oromia region of Ethiopia. The significant decrease in minimum tillage use is an indication of unsustainable adoption. The percentage of households that practice crop residue retention or mulching only has increased from about 1% to 2.4% during the two periods. However, the adoption rate is low possibly due to the alternative uses of crop residues in the Ethiopian crop-livestock mixed farming systems (Jaleta et al., 2015; Marennya et al., 2015; Tessema et al., 2015). The proportion of households who practice cereal-legume intercropping only is low and remains stable at about 3%. This indicates that monocropping is still a dominant cropping system in Ethiopian farming systems (Jirata et al., 2016). Our data suggest that Ethiopian smallholder farmers preferentially adopt minimum tillage while crop residue retention and cereal-legume intercropping lagged behind. The plausible reason could be the preferential promotion of minimum tillage by different stakeholders in the country (Jirata et al., 2016; Teklewold and Mekonnen, 2017).

⁶Crop residue retention at plot level is about 4%. Less than 1% of the households report that 35% or more of their plots are covered with crop residues or mulch.

⁷Since we do not have (sufficient) data about the crops cultivated on each plot in the previous season, we are not able to create an indicator for cereal-legume or maize-legume rotation.

What is even more surprising in our data is that the adoption of the different combinations of the CA practices is very low (Table 1). The proportion of households who practice the combination of minimum tillage and crop residue retention only (also called conservation tillage) increased from about 2.1% in 2013 to 5.5% in 2015. Nonetheless, the percentage of households who practice the combination of minimum tillage and cereal-legume intercropping only falls from 6.4% to 4.7% during the same period. The adoption of a combination of crop residue retention and cereal-legume intercropping is less than 1% in both periods. Although adoption of a comprehensive CA package that includes the full suite is theorized to provide better financial returns (Knowler and Bradshaw, 2007), the percentage of farmers practicing all components of CA (the most comprehensive CA package) is less than 1%. Previous studies also show that the adoption of the full CA package in a smallholder farming context is rare and often farmers adopt one or two individual components (Giller et al., 2009; Arslan et al., 2014; Tessema et al., 2015). The primary constraints to CA adoption include the high opportunity cost associated with the alternative use of crop residues, labor constraints and the high costs of herbicides (Arslan et al., 2014; Tessema et al., 2015; Jaleta et al., 2015; Teklewold and Mekonnen, 2017).

Since the number of households that practice a combination of crop residue retention and cereal-legume intercropping only ($T_0R_1C_1$) and the combination of the three practices ($T_1R_1C_1$) is extremely low to allow a joint analysis of the combination of these practices and produce credible estimates, our econometric model excludes the two CA categories. Estimation based on combining different categories might cloud identifying the mechanism of impact. However, we produce the impact estimates by combining the two categories with other categories as a robustness check and to minimize sample selection. The results remain similar with those obtained by dropping the two categories (see Tables 16, 17 and 18 in the Annex for combined categories and results).

Another interesting feature of CA use pattern is transition or switching behaviour of households in and out of use during the two periods. To describe the transitions of households across CA practices over the two periods, we split the CA use history for each practice and combinations into dummies. We define a “stayer” as a farmer (household) that uses the CA practice in both 2013 and 2015. A “joiner” is defined as a farmer who does not use the particular CA practice in 2013 but does in 2015. Similarly, a “leaver” is a farmer who practices the particular CA practice in 2013 but not in 2015. A “nonuser” is a household that does not use any of the CA practices in both periods. The transitions of each CA practice in the sample data is provided in Table 9 (Appendix). The results show that about 32% of the sample households used minimum tillage in both periods (stayers) and about 39% of the households switch in and out of minimum tillage use over 2013 and 2015. The use of the other CA practices in particular the combinations of CA practices is low and characterized by low transitions of households in and out of CA adoption. Such switching behaviour could be due to differences in observed and unobserved time-invariant and time-variant factors. Although we do not explicitly model CA transitions, we take account of switching behaviour and related issues in our empirical estimations.

4.3 Household poverty measures

A measure of household poverty is established using a monetary measure of household welfare. In this study, aggregate consumption expenditure is used to base the calculation of household poverty. Total household consumption expenditure is first calculated by aggregating the estimated total value of food and non-food expenditures.⁸ The aggregate consumption expenditure

⁸The value of food consumption is computed as the total value of consumption from home production, market purchases and gifts estimated using the median price. The median prices are calculated at the lowest geographical unit for which there are at least 10 price observations. If there are less than 10 price observations for that item at the enumeration area (EA), the next level up is used. The geographical levels used, in ascending order, are EA, Kebele, Woreda, zone and region and national.

is adjusted for differences in the nutritional or calorie requirement of different household members by dividing it with an adult equivalence scale. The resulting per adult equivalent nominal consumption expenditure is deflated using the consumer price index (CPI) obtained from Central Statistical Authority of Ethiopia to account for the spatial and temporal differences in the costs-of-basic needs.

Poverty indices are computed using the popular Foster-Greer-Thorbeck (FGT) method (Foster et al., 1984):

$$p_\alpha = \frac{1}{N} \sum_{i=1}^N \left[\frac{z - c_i}{z} \right]^\alpha I(c_i < z) \quad (13)$$

where z denotes the national poverty line established by the Ministry of Finance and Economic Development (MOFED) of Ethiopia, c_i is the per adult equivalent consumption expenditure estimated from the survey data for the i^{th} household, and N is the sample size. $I(c_i < z)$ is an indicator function that takes a value of 1 when the consumption of the i^{th} household lies below the national poverty line, and 0 otherwise. Three poverty indices are computed by varying the consumption inequality aversion parameter, α . When $\alpha = 0$, the formula reduces to the head count ratio that measures the proportion of households below the national poverty line. When $\alpha = 1$, it provides the poverty-gap that shows the intensity or extent of poverty in terms of how far the poor are from the national poverty line. $\alpha = 2$ provides a measure of severity of poverty that shows the degree of inequality among the poor.

In our sample, the proportion of households with consumption level below the national poverty line increased from about 41% in 2013/14 to 46% in 2015/16. The poverty headcount rate is comparable with those reported in recent studies (Zeng et al., 2015; Michler and Josephson, 2017; Verkaart et al., 2017). To better understand how the incidence of poverty changes over the two periods, we use poverty transition matrix analysis. In fact, about 66% of the households who were non-poor in 2013/14 remain above the national poverty line in 2015/16, and about 63% of the households that were poor in 2013/14 remain poor in 2015/16. This is an indication of high poverty persistence in rural Ethiopia. The result also shows the presence of a significant movement of the sample households in and out of poverty over the two periods. About 37% of the poor in 2013/14 grow out of poverty in 2015/16, whereas 34% of the non-poor in 2013/14 also slide into poverty in 2015/16. Results of the transition analysis show a dramatic mobility of the rural households into and out of poverty over the two periods. In this study, we only have two observations per household. Therefore, it is difficult to find informative measures of household poverty dynamics and to study how poverty responds to CA adoption over time. Table 2 provides the mean values of the household poverty measures. The descriptive statistics and bivariate analysis results show that non CA households are better off than CA users.

4.4 Mechanisms - farm level economic outcomes

While reducing poverty is not, strictly speaking, a direct product of CA adoption, it can be thought of as an extension of the productivity increasing, cost reducing and downside risk mitigating effects of CA. To provide evidence on the possible farm level pathways through which CA impacts household poverty, we estimate the impact of CA on farm productivity, cost of production, and risk of crop failure. Farm productivity is measured as net crop income per hectare. While crop yield per area is the most commonly used indicator for farm productivity, it is less attractive in multiple-crop economies. Since farm households are more concerned with maximization of economic value, crop income could be a better indicator to reflect the ultimate impacts of farmers' decisions (such as CA adoption) on their welfare. We take the value of crop harvested to measure value of production using prices at the most appropriate transaction level (farm gate or community levels based on data availability). Crop production expenditures are

measured as the sum of land rental values, cost of inputs including seeds, fertilizer, and labor hired for land preparation and harvest. To arrive at a measure of crop income, we deduct total production expenses from the value of production. To get a measure of the risk of crop failure, we generate a dummy variable which takes a value of 1 if the household reports any crop failure or damage in the agricultural season.

Table 2: Household welfare and farm household level economic outcomes by CA set choice

	T ₀ R ₀ C ₀	T ₁ R ₀ C ₀	T ₀ R ₁ C ₀	T ₀ R ₀ C ₁	T ₁ R ₁ C ₀	T ₁ R ₀ C ₁	Pooled
<i>Household welfare</i>							
Consumption per adult equivalent (ETB)	5267.3 (3781.9)	4969.4*** (3629.7)	4857.7 (4128.7)	4259.0*** (2664.9)	4466.2*** (2839.4)	3963.3*** (2742.5)	5002.1 (3627.3)
Poverty headcount index	0.398 (0.489)	0.436*** (0.496)	0.529*** (0.502)	0.533*** (0.500)	0.483** (0.501)	0.583*** (0.494)	0.433 (0.496)

Poverty severity index	0.054 (0.114)	0.070*** (0.131)	0.107*** (0.161)	0.097*** (0.162)	0.078*** (0.134)	0.125*** (0.177)	0.068 (0.130)
<i>Farm level outcomes - mechanisms</i>							
Net crop income per hectare (ETB)	8200.6 (10133.9)	7327.4*** (9078.6)	9240.6 (9255.9)	9089.3 (8925.3)	8269.0 (9745.1)	6423.7*** (7304.3)	7729.6 (9428.9)
Crop production costs per hectare (ETB)	1128.9 (1643.2)	802.4*** (1290.8)	985.5 *** (1103.4)	687.2*** (922.2)	832.6 (916.7)	681.9*** (1143.5)	919.0 (1410.9)
Crop failure (1=Yes)	0.787 (0.409)	0.772 (0.420)	0.894*** (0.309)	0.894 *** (0.308)	0.838* (0.369)	0.885*** (0.320)	0.794 (0.405)
Observations	2,664	2,543	104	180	230	338	6,059

Note: T, R and C refer to Minimum tillage, crop residue retention and cereal-legume intercropping respectively. The subscripts '0' and '1' denote use and non use, respectively. ETB is Ethiopian Birr. Mean differences are based on the no CA category as a reference. Standard errors in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 2 shows that there is a considerable difference in crop income and cost of production per hectare between CA and non CA households. The bivariate analysis shows that the average net crop income per hectare ranges between 6,423.70 and 9,240.60 Ethiopian Birr (ETB). The per hectare cost of production also ranges between 681.90 and 1,128.90 ETB. The result shows that CA users have lower cost of production than non CA households. Cereal-legume intercropping is the cheapest CA technology set followed by combination of minimum tillage and cereal-legume intercropping. Households practicing almost all CA components report higher crop failure compared to non CA households. While informative, results from mean comparison across CA users and non-users helps less to infer causal relations due to differences in observable and unobservable characteristics between the two groups.

5 Econometric Results

In this section, we first discuss the first stage results of the panel data endogenous switching multinomial logit model which provides estimates for the determinants of CA adoption. This is followed by discussion of the impact of CA on poverty and the farm level economic outcomes.

5.1 Drivers of CA use

The parameter estimates (marginal effects) of the first stage multinomial endogenous switching regression which allow us to explore the main determinants of CA adoption are given in Table 11 (Appendix). The results provide information on the drivers of CA adoption. The Wald test result ($\chi^2 = 1612.35$, significant at 1% level) suggests that the explanatory variables included in the model provide a good explanation of CA choice behaviour. The Mundlak variables (individually and jointly) are significant in the multinomial logit model. This indicates the presence of some sort of unobserved heterogeneity and justifies the use of the pooled multinomial logit model with farmer's heterogeneity.

Household and farmer characteristics play a minimal role in determining CA use. Household size (measured in adult equivalents) increases the probability of cereal-legume intercropping with no significant effect on the other CA pillars. Land holding is found to be positively correlated with the probability of crop residue retention and cereal-legume intercropping only. Access to credit is positively associated with crop residue retention. In rural areas where crop residues are one source of household income, credit access may relax liquidity constraint and allows retention of crop residues as mulch. Age of the household head is negatively associated with adoption of minimum tillage only. This could be attributed to impatience, risk aversion and technology mistrust behaviour (Bezu et al., 2014; Verkaart et al., 2017). Arslan et al. (2014) also find a negative correlation between age of the household head and conservation farming adoption in Zambia. Agricultural asset wealth reduces the probability of crop residue retention but increases the probability of adopting a combination of minimum tillage with cereal-legume associations. This finding is consistent with that of Asfaw et al. (2016a) that also find a negative correlation between agricultural asset wealth and crop residue retention in Niger. Surprisingly, we find little evidence regarding the role of livestock holding on the probability of CA use. We find no evidence for the role of gender and education of the household head in determining CA use decision.

We explore the role of extension service or advice on crop production and natural resources management in determining CA use. While increase in the quality of advice on crop production reduces the probability of crop residue retention, advice on natural resources management increases the use of both crop residue retention and conservation tillage. The positive and significant effect on conservation tillage is corroborated by previous findings (Arslan et al., 2014; Di Falco and Veronesi, 2013). The adoption of minimum tillage and the combination of minimum

tillage with cereal-legume intercropping is positively associated with distance to the nearest market. This could be due to the desire for food self-sufficiency, particularly in areas where markets cannot be easily accessed. We find distance to the nearest major road to be negatively associated with adoption of cereal-legume intercropping only. Since proximity to major road is often associated with improved transportation and information, remote households may lack information about the benefits of CA. CA use is negatively associated with input price increase. This suggests that increase in price of agricultural inputs deters adoption of CA.

Farm characteristics and soil nutrient availability are also found to be important determinants of CA use. Interestingly, farm households who face minimal soil nutrient constraints are less likely to adopt minimum tillage. Furthermore, the adoption of crop residue retention and conservation tillage is negatively correlated with the number of plots with good fertility. The results suggest that households are more likely to adopt these CA practices as a strategy to alleviate soil nutrient constraints. This finding is in line with results from previous studies (Di Falco and Veronesi, 2013; Arslan et al., 2014; Asfaw et al., 2016a). The use of organic fertilizer increases the probability of minimum tillage adoption but reduces the probability of adopting conservation tillage. This could be possibly due to potential complementarity or substitutability between organic fertilizer and CA practices.

Consistent with the literature, we find that most of the climatic variables have a significant effect on CA choice. An increase in monthly temperature positively and significantly affects all CA practices except conservation tillage. Although the rainfall level in the previous agricultural season does not exert significant effect on CA adoption, an increase in the historical average rainfall reduces the adoption of cereal-legume intercropping and conservation tillage. More importantly, long-term rainfall variability measured using standard deviation increases the probability of adoption of crop residue retention, cereal-legume intercropping and the combination of minimum tillage with cereal-legume intercropping. This suggests that households who receive higher annual rainfall do not have an incentive to adopt CA, an indication that CA is an attractive strategy in times of rainfall stress. The statistical significance of the relationship between the climatic variables and the adoption of CA suggests that CA could be a strategy adopted by farmers in response to climatic variability (Di Falco and Veronesi, 2013; Arslan et al., 2014; Teklewold and Mekonnen, 2017).

5.2 Impacts of CA on Poverty

We estimate the impact of CA on three household poverty indices: headcount, poverty gap, and poverty severity. Results from the econometric models show that some of the time averages, the selection correction terms, and interaction of the selection bias correction terms with time are significant in most of the outcome equations. This is an indication of the presence of selection bias and unobserved heterogeneity in the CA use decisions. It also justifies the appropriateness of the selected empirical strategy to attenuate endogeneity. Since the interest is on the impact estimates of CA on poverty, the second stage outcome regressions are not discussed here. The second stage regressions estimates for the three poverty indices are provided in the Appendix (see Tables 12, 13 and 14). Table 3 provides the actual and counterfactual outcomes and the treatment effect estimates (ATT) from the panel data multinomial endogenous switching regression.

Table 3: Impact of CA on household poverty

CA set	Poverty headcount			Poverty gap			Poverty severity		
	A	C	ATT (A-C)	A	C	ATT(A-C)	A	C	ATT(A-C)
Minimum tillage	0.436	0.439	-0.004	0.149	0.154	-0.005*	0.070	0.075	-0.005***
Crop residue retention	0.529	0.388	0.141**	0.210	0.153	0.057**	0.107	0.067	0.040**
Cereal-legume intercropping	0.533	0.598	-0.065*	0.192	0.230	-0.038*	0.097	0.123	-0.026*
Min. tillage & crop residue	0.483	0.408	0.075***	0.165	0.149	0.018*	0.078	0.067	0.010*
Min. tillage & cereal-legume	0.580	0.783	-0.203***	0.237	0.334	-0.097***	0.125	0.175	-0.050***

Note: We report actual outcome with CA (A), counterfactual outcome without CA scenario (C) and difference in actual and counterfactual outcomes as impact (ATT). We do not report standard errors to save space. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Estimates from the panel data endogenous switching regression show that minimum tillage individually does not exert any significant effect on poverty headcount. However, crop residue retention increases the probability of being poor. Cereal-legume intercropping reduces the probability that a household falls below the national poverty line by 6.5 percentage points. The combined use of minimum tillage and crop residue retention, also known as conservation tillage, also increases the probability of being poor by about 7.5 percentage points. An interesting finding is that, the combined use of minimum tillage with cereal-legume intercropping reduces the probability of being poor by 20.3 percentage points. The findings show that CA indeed has a poverty-reducing effect. However, this role depends on the type of CA practice.

Table 3 also provides evidence on the link between CA and other poverty indices. An interesting result is the significant effect of minimum tillage in reducing both poverty gap and poverty severity. However, crop residue retention and the combination of crop residue retention and minimum tillage appear to be least attractive options for reducing poverty gap and poverty severity in Ethiopia. Cereal-legume intercropping and more importantly the combination of minimum tillage with cereal-legume intercropping unambiguously reduce both poverty gap and poverty severity. The totality of our findings suggests that having crop residues in the CA technology set is less likely to help households grow out of poverty at least in the short run.

Studies from SSA emphasize that the benefits of CA are context specific (Giller et al., 2009; Pannell et al., 2014; Arslan et al., 2015). Pannell et al. (2014) argue that CA would be more attractive to households with better resource endowments and with longer planning horizons or lower discount rates. There is also a possibility that some households are positioned well and have the capacity to benefit from the CA while others do not (Dercon and Christiaensen, 2011; Verkaart et al., 2017). In this study, we test whether CA generates differential effect on poverty for households with different resource endowments and exposure to rainfall shocks (Table 4). Differences in resource endowments determines differences in risk tolerance and the opportunity cost of climate risk for households (Hansen et al., 2018). Analyzing the differential impacts of CA based on differences in exposure to rainfall endowment (rainfall stress or rainfall shortage and rainfall abundant or rainfall surplus) could help to explain whether CA reduces rural poverty through its resilience benefits.⁹

⁹We follow Ward and Shively (2015) and Michler et al. (2018) to measure rainfall shock. We construct rainfall shortage as: $\underline{r}_{it} = \left| \frac{R_{it} - \bar{R}_i}{\sigma_{it}} \right|$ if $R_{it} < \bar{R}_i$, 0 otherwise. A measure of rainfall surplus is computed as: $\bar{r}_{it} = \left| \frac{R_{it} - \bar{R}_i}{\sigma_{it}} \right|$ if $R_{it} > \bar{R}_i$, 0 otherwise. R_{it} is the yearly rainfall, \bar{R}_i is the historical average (1981-2014), and σ_{it} is the standard deviation of rainfall during the same period.

Table 4: Effects of CA on poverty headcount by rainfall and household wealth

CA set	Rainfall shock		Livestock holding		Land holding	
	shortage	surplus	poor	non-poor	poor	non-poor
Minimum tillage	-0.022***	0.013	-0.012	0.003	0.002	0.008
Crop residue retention	0.104	0.202	0.100	0.147*	0.032	0.216***
Cereal-legume intercropping	-0.061	-0.070	-0.098	-0.081*	-0.184*	0.048
Min. tillage & crop residue	0.031	0.189***	-0.019	0.127***	0.039	0.108***
Min. tillage & cereal-legume	-0.206***	-0.196***	-0.196***	-0.206***	-0.280***	-0.095***
Observations	3,914	2,188	1,971	4,131	1,924	4,178

Note: We report only the ATT (difference in actual outcome and counterfactual outcome) to save space. Livestock and land poor are households with livestock holdings (in TLU) and land holdings (hectares) in the lowest (first) quartile of the distribution and non-poor are those with livestock holdings and land holdings in the second, third and fourth quartiles; * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The results disaggregated by rainfall endowments show that the poverty-reducing effects of CA, particularly minimum tillage, are more pronounced in areas that experience rainfall shortage than in areas that have abundant rainfall. The combination of minimum tillage and cereal-legume intercropping reduces poverty regardless of differences in rainfall endowments. The results are in compliance with findings from previous studies (Lobell et al., 2008; El-Shater et al., 2016). Teklewold and Mekonnen (2017) also show that reduced tillage provides higher farm returns in drier areas in Ethiopia. While crop residue retention and cereal-legume intercropping alone do not have any significant effect on household poverty in areas with different rainfall endowments, the combined use of minimum tillage and crop residue retention increases the probability of being poor in areas experiencing rainfall surplus. This is an indication that conservation tillage is not an attractive CA option in these areas and this could be due to potential yield penalty (Michler et al., 2018). Pannell et al. (2014) also indicate the possible cases of short-term yield depression associated with the use of reduced tillage and mulching.

Disaggregating the results by different wealth (land and livestock holding) groups provides some interesting findings. As expected, crop residue retention and conservation tillage do not increase the likelihood of being poor for households with low livestock and land holdings (those at the lowest quartiles). However, it increases the probability of falling below the poverty line for households with more livestock and land holdings. This is evidence that relatively rich households do not have an incentive either to leave crop residues as mulch on their farms or to combine minimum tillage with crop residue retention. We find that cereal-legume intercropping has marginal poverty-reducing effect among livestock non-poor and land-poor households. This latter result is interesting because cereal-legume intercropping is itself a land-saving practice in land-constrained circumstances. The results show that this CA pillar has significant poverty reducing effects for households with land holdings at the lowest quartile (poor households) compared to richer households. The unambiguously negative and significant poverty reducing effect of the combination of minimum tillage with cereal-legume intercropping makes it the most attractive CA option for reducing rural poverty and hence improving rural prosperity in Ethiopia.

5.3 Impact Pathways

To elucidate the potential mechanisms through which CA affects poverty, in the following section, we empirically explore if CA also has significant effect on crop income, cost of production and risk of crop failure.

5.3.1 Farm productivity effects of CA

The estimates of the multinomial endogenous switching regression model for farm productivity measured as net crop income per hectare is provided in Table 5. The results show that minimum tillage increases net crop income per hectare by about 2,724 Ethiopian Birr (ETB). While crop residue retention reduces the per hectare crop income by about 5,024 ETB, cereal-legume intercropping alone or conservation tillage do not have any significant effect on crop income.

Table 5: Impact of CA on crop income per hectare

CA set	Actual Outcome	Counterfactual Outcome	Impact (ATT)
Minimum tillage	7,528.15	4,804.19	2,723.96*** (162.62)
Crop residue retention	9,781.43	14,804.94	-5,023.51*** (1432.79)
Cereal-legume intercropping	9,160.04	9,366.14	-206.11 (670.59)
Minimum tillage & crop residue	8,559.12	8,640.52	-81.40 (640.49)
Minimum tillage & cereal-legume	6,418.52	1,210.90	5,207.62*** (847.61)

Note: ATT stands for average treatment effect on the treated and computed as the difference in actual and counterfactual outcomes. We do not report standard errors for actual and counterfactual outcomes to save space. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Interestingly, we find that CA generates higher farm productivity benefits when minimum tillage is used in combination with cereal-legume intercropping, increasing the average crop income by about 5,208 ETB per hectare for users compared to the counterfactual scenario of non use. The significant farm productivity or crop income effects of CA are consistent with the findings of previous studies (Jaleta et al., 2016; Khonje et al., 2018). Farris et al. (2017) also demonstrate that CA reduces poverty in Uganda by increasing farm profits for the poor households. Recently, Khonje et al. (2018) find that CA increases maize yield, maize income and household income in Zambia when adopted in isolation as well as in combination with improved seeds. Our finding is also in agreement with previous studies that document the positive welfare impact of minimum tillage and cereal-legume intercropping (Mason and Smale, 2013; Zeng et al., 2015).

5.3.2 Impact of CA on cost of production

The estimates for the impact of CA on the cost of production are provided in Table 6. With the exception of crop residue retention, we find that all CA practices (when used in isolation) and a combination of minimum tillage with crop residue and cereal-legume intercropping have significant production cost reducing effects. Part of the reason for the significant cost-reducing effects of minimum tillage could be its labor demand reducing effect (Knowler and Bradshaw, 2007; Teklewold et al., 2013; Teklewold and Mekonnen, 2017). Cereal-legume intercropping also plays a pivotal role in the control of crop pests, diseases and weeds, and legumes also provide nitrogen to cereal crop production through their nitrogen-fixing role. Thus, cereal-legume intercropping could reduce the demand for pesticides and chemical fertilizer, inputs that often contribute the highest costs of crop production (Teklewold et al., 2013; Kassie et al., 2017). Nevertheless, crop residue retention involves costs for herbicides and labor for weed control, particularly when combined with minimum tillage.

Table 6: Impact of CA on cost of production

CA set	Actual Outcome	Counterfactual Outcome	Impact (ATT)
Minimum tillage	803.46	1,288.25	-484.79*** (19.03)
Crop residue retention	985.45	815.38	170.08 (157.43)
Cereal-legume intercropping	687.18	1,454.38	-767.20*** (146.07)
Minimum tillage & crop residue	832.56	998.06	-165.50*** (44.43)
Min. tillage & cereal-legume intercropping	683.11	1,092.10	-409.00*** (49.83)

Note: ATT stands for average treatment effect on the treated and computed as the difference in actual and counterfactual outcomes. We do not report standard errors for actual and counterfactual outcomes to save space. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

The lack of significant effect of crop residue retention on the cost of production (although not expected as discussed in [Pannell et al. \(2014\)](#)), coupled with its negative impact on crop income, could explain why it is not an attractive strategy for reducing rural poverty at least in the short run.

5.3.3 Impact of CA on risk of crop failure

In areas plagued by low rainfall and poor soil fertility that increase the level of environmental stress, CA can improve the adaptive capacity or resilience of households through reducing the risk of crop failure ([Di Falco and Chavas, 2008](#)). We find that the adoption of minimum tillage in isolation reduces the probability of crop failure by 1.6 percentage points compared to the counterfactual scenario. However, crop residue retention, cereal-legume intercropping and conservation tillage have no significant impact on the probability of crop failure. The results show that the combination of minimum tillage and cereal-legume intercropping has the highest impact on reducing the risk of crop failure (6.2 percentage points). Previous studies also demonstrate that the risk-reducing (and other) benefits of CA are mainly driven by cereal-legume intercropping and the interaction of minimum tillage with cereal-legume associations ([Thierfelder et al., 2013](#); [Kassie et al., 2015](#); [Arslan et al., 2015](#)).

Table 7: Impact of CA on risk of crop failure

CA components	Actual Outcome	Counterfactual Outcome	Impact (ATT)
Minimum tillage	0.773	0.789	-0.016***
Crop residue retention	0.894	0.882	0.012
Cereal-legume intercropping	0.894	0.906	-0.011
Minimum tillage & crop residue	0.838	0.815	0.023
Minimum tillage & cereal-legume intercropping	0.887	0.949	-0.062***

Note: ATT stands for average treatment effect on the treated and computed as the difference in actual and counterfactual outcomes. We do not report standard errors for actual and counterfactual outcomes to save space. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Overall, the results strongly suggest that the main mechanisms for poverty-reducing effects of CA (particularly minimum tillage, cereal-legume intercropping or their combination) could be increased crop income, reduced cost of production and reduction of the risk of crop failure.

6 Conclusion

Climate-induced shocks are common occurrences in developing countries with negative consequences on the welfare and adaptive capacity of rural households. Conservation agriculture

(CA) is one of the climate smart agricultural practices receiving increasing attention in SSA as a panacea to the problems associated with conventional agriculture. In an environment characterized by repeated exposure to exogenous shocks and poor soils, CA could be an effective strategy for reducing the risk of crop failure associated with climatic factors, improving soil fertility and increasing household welfare. Using recent panel data from Ethiopia and historical weather data, this study assesses the impact of CA on household poverty. A multinomial endogenous switching regression model in a panel data framework is used to control for potential selection bias and endogeneity of the choice to use CA.

This study provides up-to-date evidence on the drivers of CA use in Ethiopia and the potential incentives for its wider scale adoption. We find evidence that the use of CA in Ethiopia is generally low, uneven and unstable. Surprisingly, the use of a combination of CA practices is rare. Among the strongest determinants of CA choice are climatic factors (rainfall and temperature), soil nutrient constraints, and the enabling environment (such as proximity to markets and extension service). The study provides evidence that a shift away from conventional farming to the increased use of CA can potentially reduce the incidence and depth of rural poverty. Minimum tillage, the most prevalent component of CA, has an attractive welfare benefit when used either alone or in combination with cereal-legume intercropping. However, our study finds that crop residue retention and its combined use with minimum tillage is not an attractive CA option for reducing rural poverty. This latter finding may explain why there is low uptake of some of the CA practices in Ethiopia in particular and in SSA at large. Disaggregating the results by rainfall and wealth endowments, we find evidence that minimum tillage and its combined use with cereal-legume intercropping have poverty-reducing benefits in areas experiencing rainfall stress and for households in the lowest quartile of land holding distribution. This is an indication that CA insulates households from welfare risk in less-favored areas prone to climate shocks and for resource poor households. Crop residue retention and conservation tillage increase the probability of being poor, particularly for relatively rich households. The results also show that CA practices that reduce rural poverty are those that increase crop income, reduce the cost of production and mitigate the risk of crop failure. Overall, combined use of minimum tillage and cereal-legume intercropping is the most attractive agronomic practice that could be adopted by farmers as an *ex-ante* strategy to improve agricultural performance, reduce exposure to production risks and improve household welfare.

While the study provides evidence that can be used to promote the wider scale adoption of CA, the policy question is how to make CA work for the poor. Looking at the effects of CA across different subgroups of farmers, we separate out farm households and specific CA practices that should be targeted by policy interventions. Our findings suggest the need to target promotion of CA practices that generate higher poverty reduction benefits than a rigid recommendation. From a policy perspective, alleviating the barriers to the adoption of CA requires improving access to knowledge and information about CA. Since the agricultural extension system is the common channel through which technologies such as CA reach the wider community, there is a need for building the capacity of CA implementing agencies, mainly the extension services. Moreover, there is a need for creating knowledge platforms where farmers could learn about the benefits of CA that are appropriate to their local conditions. If climate-smart practices such as CA are to work for the poor, development and climate finance programs need to shift their focus towards improving the incentives for resource-poor smallholder farmers to invest in CA practices that hold the potential for improving farm productivity, resilience and reduce rural poverty.

Although the findings in this chapter are informative and stimulate further studies, lack of data has been a constraint to increasing the rigor of the study. This stems from the fact that the LSMS-ISA is a multi-purpose survey and finding detail information on CA is difficult. The other

caveat of the study primarily emanates from a limitation on the way CA use is measured. In our study, CA is an indicator variable that differentiates whether a household practices any of the three CA practices (minimum tillage, crop residue retention, or cereal-legume intercropping) or a mix of them. However, this measure might capture only partial CA use and does not measure the intensity of CA use. The analysis presented in this paper is based on short panel which does not allow investigating the variation in CA use and its welfare impact in detail. With this caveat in mind, further research using detailed panel data is suggested to provide better evidence on the topic and to improve our understanding of the viability of CA and its welfare impact. In semi-subsistence agricultural production system where farm households are both producer and consumer of their produce, improved agricultural practices such as CA would have both direct and indirect effects. In particular, CA can have effects that transcend the individual (private) decision maker. While we attempt to explore the direct effect of CA on poverty, future research is needed to capture its indirect (and societal) effects to provide a better picture of the aggregate or net effects.

7 Appendix

Table 8: Proportions of households practicing CA (%)

CA technology set	2013	2015	Pooled
Minimum tillage	0.595 (0.491)	0.432*** (0.495)	0.514 (0.500)
Crop residue or mulch	0.035 (0.184)	0.089*** (0.285)	0.062 (0.241)
Cereal-legume intercropping	0.107 (0.310)	0.097 (0.296)	0.102 (0.303)
Minimum tillage & crop residue	0.023 (0.150)	0.061*** (0.240)	0.042 (0.201)
Minimum tillage & cereal-legume	0.066 (0.248)	0.054** (0.225)	0.060 (0.237)
Crop residue & cereal-legume	0.004 (0.065)	0.010*** (0.099)	0.007 (0.084)
Min. tillage, crop residue & cereal-legume	0.002 (0.044)	0.007*** (0.083)	0.004 (0.066)

Note: Standard deviations in parentheses; * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$. Proportion (mean) difference tests are based on 2013 as a reference. The CA sets are not mutually exclusive. The sample size is 3075 and 3027 for 2013 and 2015 respectively.

Table 9: Transitions in CA use over the sample periods 2013 and 2015 (%)

CA practices	Stayers	Leavers	Joiners	Nonusers
Minimum tillage	32.1	27.0	11.8	29.1
Crop residue retention	0.3	2.8	8.8	88.1
Cereal-legume intercrop	3.3	6.6	5.2	84.9
Min. tillage & crop residue	0.1	1.7	6.3	91.9
Min. tillage & cereal-legume intercropping	1.8	5.0	3.4	89.9
Crop residue & cereal-legume intercropping	0.0	0.4	1.0	98.6
Comprehensive CA package (all 3 practices)	0.0	0.2	0.7	99.1

Note: Results are based on a balanced sample of 5630 households (2815 in each period).

Table 10: Household characteristics by CA sets

Note: T, R and C refer to Minimum tillage, crop residue retention and cereal-legume intercropping respectively. The subscripts '0' and '1' denote use and non use, respectively. We report actual outcome with CA (A), counterfactual outcome without CA scenario (C) and difference in actual outcome and counterfactual outcome as impact (ATT). We do not report standard errors to save space. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Table 17: Distributional effects of CA on poverty incidence (headcount) by rainfall and household wealth

CA set	Rainfall shock		Livestock holding		Land holding	
	shortage	surplus	poor	better-off	poor	better-off
$T_1R_0C_0$	-0.022***	0.012	-0.013	0.003	0.001	0.008
$T_0R_1C_0/T_0R_1C_1$	0.147	0.264*	0.077	0.230**	0.136	0.230***
$T_0R_0C_1$	-0.065	-0.078	-0.105*	-0.085**	-0.193*	0.045
$T_1R_1C_0/T_1R_1C_1$	0.043	0.185***	0.018	0.115***	0.063	0.094***
$T_1R_0C_1$	-0.205***	-0.197***	-0.197***	-0.206***	-0.282***	-0.095***

Note: T, R and C refer to Minimum tillage, crop residue retention and cereal-legume intercropping respectively. The subscripts '0' and '1' denote use and non use, respectively. We report only the ATT (difference in actual outcome and counterfactual outcome) only. Standard errors are not reported to save space. Livestock and land poor are households with livestock holdings (TLU) and land holdings (hectares) in the lowest (first) quartile of the distribution and non-poor are those with livestock holdings and land holdings in the second, third and fourth quartiles; * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.
